Interventions for people bereaved through suicide: systematic review
Catriona McDaid, Rebecca Trowman, Su Golder, Keith Hawton and Amanda Sowden

Background
Promoting the mental health of people bereaved through suicide is a key aim of the National Suicide Prevention Strategy.

Aims
To evaluate the effects of interventions to support people bereaved through suicide.

Method
We conducted a systematic review of data from controlled studies of interventions for people bereaved through suicide. Studies were identified using systematic searches, the methodological quality of included studies was assessed and narrative synthesis conducted.

Results
Eight studies were identified. None was UK-based and all but one study had substantial methodological limitations. When compared with no intervention, there was evidence of some benefit from single studies of a cognitive–behavioural family intervention of four sessions with a psychiatric nurse; a psychologist-led 10-week bereavement group intervention for children; and 8-week group therapy for adults delivered by a mental health professional and volunteer. The findings from studies comparing two or more active interventions were more equivocal.

Conclusions
Although there is evidence of some benefit from interventions for people bereaved by suicide, this is not robust. Further methodologically sound evidence is required to confirm whether interventions are helpful and, if so, for whom.

Declaration of interest
None. Funding detailed in Acknowledgements.

Suicide is a major public health issue. During 2002–2004 (latest available data) there were 8.6 suicide deaths per 100 000 population in England, with the majority occurring in young adult males. The global mortality rate is estimated at 16 per 100 000— one death every 40 seconds. For every suicide it has been estimated that six people will experience intense grief, which extrapolates to around 35 000 persons in the UK annually. Promoting the mental health of people bereaved through suicide is a key aim of the National Suicide Prevention Strategy. Although the effects of such a bereavement are not necessarily more severe than bereavement following other causes of death, there are certain aspects such as stigmatisation and a sense of rejection that may make coping particularly difficult. A distinction has been drawn between normal grief and complicated grief where there is persistent yearning for the deceased that is severe and disruptive to normal life. Such a response may be more common after deaths such as suicide. Diagnostic criteria have been proposed for inclusion in the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders: at least four of eight specific symptoms must be experienced frequently and/or be severely distressing for at least 6 months.

Sources of support for those bereaved through suicide include general practitioners, specialised therapists, self-help groups, specialised reading material and internet sites. However, little is known about the effects of providing support. We conducted a systematic review with the purpose of evaluating the effects of interventions to assist people bereaved by suicide in dealing with the impact of the death and the consequences for their well-being.

Method

Literature search
Over 30 databases and other sources were searched up to 1 October 2007, including Medline, EMBASE, PsycINFO and the Science Citation Index, as well as sources of grey literature and ongoing studies. No language restriction was applied. Details of the search strategy and the databases searched are available from the authors. We checked reference lists of all the potentially relevant papers and contacted organisations and experts in the field. Two reviewers independently screened the search results for eligible studies. Disagreements were resolved by consensus or through consultation with a third reviewer.

Inclusion criteria
Any type of intervention targeted at adults or children bereaved through suicide was eligible for inclusion, for example support groups, self-help and volunteer-led groups, as well as therapeutic interventions delivered by health professionals. There was no restriction on the relationship to the person who had died: studies of people bereaved through a personal or professional relationship were also eligible. All outcomes (qualitative and quantitative) were considered relevant. The key restriction was that only randomised controlled trials (RCTs) and studies with a control or comparison group (including cohort studies) were eligible. This was viewed as particularly important owing to the changing nature of grief over time.

Data extraction and quality assessment
Key study characteristics and outcomes were extracted and studies were quality-assessed by one reviewer and checked for accuracy by a second. Disagreements were resolved through consensus, and if necessary a third reviewer was consulted. One French-language paper required translation. The quality criteria (see Appendix) were based on the Centre for Reviews and Dissemination’s guidance for undertaking systematic reviews, and a report on evaluating non-randomised studies. In order to assess the integrity of the intervention we drew on the Quality Assessment Tool for Quantitative Studies. 10

Data synthesis

Given the diversity of the studies in terms of settings, interventions, outcomes and outcome measures used, we undertook a narrative synthesis based on recent guidance.\textsuperscript{11,12} The primary study findings were interpreted, and similarities and differences between the studies investigated. This included consideration of study design, methodological quality, whether the study was appropriately powered, intervention characteristics and delivery, participants and outcome measures. Studies were grouped according to whether they had an active comparison group.

Results

Study characteristics

Eight studies met the inclusion criteria (Fig. 1).\textsuperscript{13–20} There were four RCTs,\textsuperscript{15–17,20} one controlled study,\textsuperscript{16} and three observational studies with a control group,\textsuperscript{13,14,19} one of which was retrospective\textsuperscript{14} (online Table DS1). No UK-based study was identified. In the majority of studies the participants were members of the dead person’s family, although two studies focused on school or university students. There were four studies of adults only,\textsuperscript{13,14,16,19,20} and one of children only.\textsuperscript{13} Two included a small number of children in their comparison group,\textsuperscript{14,18} and in one, outcome was reported separately for adults and children.\textsuperscript{17} In most studies the majority of participants were women. Where ethnic data were reported, participants were predominantly White.\textsuperscript{14–17} Data on other participant-related potential prognostic factors were not reported consistently across the studies. Baseline scores on some key scales (where available) are reported in online Table DS1 and data from other measures used are available from the authors. Participants were recruited by researchers,\textsuperscript{16,17,20} professional referral,\textsuperscript{13,14} and multiple sources such as self-referral and professional referral.\textsuperscript{13,15,18,19}

The studies had few inclusion or exclusion criteria (online Table DS1) and none of the studies selected participants on the basis of vulnerability to mental health problems such as depression or complicated grief. None of the included studies investigated interventions targeted at professionals such as emergency services personnel or health professionals. Although most studies used standardised outcome measures, there was little consistency in the measures chosen: three used the Beck Depression Inventory (BDI) and two the Impact of Event Scale (IES). Owing to the diversity of assessment instruments, it was difficult to assess the baseline similarity of participants across studies. Apart from three studies,\textsuperscript{15,19,20} the length of follow-up was less than 1 year. It is unlikely, therefore, that participants were followed long enough to allow a meaningful assessment of outcome in most studies.

The settings in which the interventions occurred were also diverse and included a school,\textsuperscript{13} the family home,\textsuperscript{20} the scene of the suicide,\textsuperscript{14} a laboratory at a university,\textsuperscript{16} and a suicide prevention centre.\textsuperscript{18,19} Two studies did not report any details about the setting.\textsuperscript{15,17} With the exception of one study,\textsuperscript{16} the interventions were delivered in a family or group context by mental health professionals\textsuperscript{15,17,19,20} or by mental health professionals in conjunction with volunteers who had themselves been bereaved by suicide.\textsuperscript{13,18}

Quality

With the exception of the study by de Groot et al.,\textsuperscript{20} substantial methodological problems were identified in the studies. The key threats to study validity are summarised in Table 1; the full quality appraisal is available from the authors.

Two of the RCTs were truly random,\textsuperscript{15,20} one was not (participants were assigned in alternating order),\textsuperscript{17} and one did not report how randomisation was carried out.\textsuperscript{16} One RCT attempted to conceal treatment allocation.\textsuperscript{20} There is therefore the risk that the effectiveness of the interventions was overestimated in the other studies, especially given that subjective outcome measures were used. The remaining studies used various methods to assign participants to the intervention and comparison groups, all of which had a high risk of selection bias. There were differences between groups at baseline in three studies,\textsuperscript{16–18} or it was unclear whether they were similar.\textsuperscript{13,15} None of the studies appeared to conduct a full intention-to-treat analysis including all allocated participants. In some situations this can lead to an overestimation of the treatment effect, but it is worth noting that in the study by de Groot et al those who dropped out had slightly more favourable scores at baseline for depression, complicated grief and self-blame.\textsuperscript{20}

The studies were generally small and, with the exception of the de Groot et al study,\textsuperscript{20} it was unclear whether they were appropriately powered to detect an effect on all the outcomes measured. Four of the studies indicated (explicitly or implicitly) that the intervention was implemented based on a treatment protocol or manual.\textsuperscript{15–17,20} It was possible to assess the fidelity of the intervention in only one study, which measured consistency of delivery.\textsuperscript{17} Hence, there is the question of whether the intervention and comparison were delivered as planned, and in a consistent manner.

Study findings

Intervention v. no intervention

There was some evidence of a positive effect of interventions when compared with no intervention (Table 1). A 10-week bereavement group intervention for children, led by psychologists, was more effective than no intervention at reducing anxiety and depression, but not social adjustment and post-traumatic stress.\textsuperscript{17} This was a small study and it was unclear whether it was appropriately powered to detect an effect on the outcomes measured. In addition, a fifth of the comparison group sought other interventions, which might have diluted or inflated the effect of the intervention.
There were also differences between the groups at baseline: children in the intervention group were younger, had better social adjustment and the length of time since bereavement was shorter.

An 8-week group therapy intervention delivered by a mental health professional and a volunteer was associated with a lessening of eight of nine emotions assessed compared with one for the intervention group compared with controls. There was a statistically significant benefit for the intervention group compared with control in perception of being to blame for the suicide.20 There was also a greater reduction in anxiety (RCMAS) and depression (CDI) at 12 weeks for children who received the intervention compared with those who did not (statistically significant), but not for social adjustment (SAICA), post-traumatic stress (CPSRI) or parental depression (BDI).

The third study was a cluster randomised trial of family-based cognitive–behavioural therapy (CBT), compared with usual care, for first-degree relatives and spouses.21 The intervention consisted of four sessions of CBT with a trained psychiatric nurse counsellor, 3–6 months following the bereavement. This was the best-quality study found: there was an adequate method of randomisation, an appropriate method was used to adjust for baseline differences and loss to follow-up was low. Thirty months after the bereavement there was no beneficial effect on the primary outcome of self-reported complicated grief reaction (measured by the Inventory for Traumatic Grief) or on suicidal ideation or depression in the intervention group compared with controls. There was evidence, however, of fewer maladaptive grief reactions and less perception of being to blame for the suicide.20

Studies using an active comparator

The findings from the studies comparing two or more active interventions were equivocal (Table 2). Among undergraduates, writing therapy over a 2-week period which involved describing

There was a statistically significant benefit for the intervention group compared with control in perception of being to blame (adjusted OR=0.18, 95% CI –0.05 to 0.67, P=0.82) and shame and guilt than the comparison group. The reliability and validity of the outcome measure were unclear. The time lapse to bereavement and attending a crisis centre for assessment and treatment was shorter in those who had received an active outreach intervention at the scene of the suicide compared with those who had not;14 however, this outcome measure is based on the assumption that seeking help following the intervention is a positive outcome. In the absence of any information about individuals who received the outreach intervention but did not seek help at the crisis centre, it is unclear whether this was an appropriate assumption.

the events and emotions around their loss had some marginal benefits compared with a trivial writing condition. However, participants in the profound writing group also had less severe grief than the comparison group at baseline. In a school setting, implementation of a crisis intervention involving first talk through and psychological debriefing was associated with fewer pupils experiencing high-intensity grief, but not stress response, than a less intense crisis intervention. A study comparing four groups led, closed-group interventions of 2 months, 4 months, 6 months and 12 months duration reported a trend in prevention that was significant for all four groups towards decreasing depression over the 12-month period. There was some variation between groups in all four groups towards decreasing depression over the 12-month period.

### Discussion

Despite extensive searches, no language restrictions and broad inclusion criteria we identified only eight eligible studies, none of which focused on health professionals.

### Interpretation of results

Six of the eight studies showed some evidence of benefit for participants receiving the intervention on at least one measure. However, because of the differences between studies and the methodological limitations, considerable care needs to be taken before accepting the assumption that some kind of intervention is better than none. Some of the methodological limitations, such as small sample size or the control group receiving support from elsewhere, might have resulted in the treatment effect being underestimated. However, the latter might also have led to an
The review is limited by the small number of studies available, their diversity and general poor quality. This reflects the findings of a systematic review of bereavement care interventions for general population groups, where the authors reported considerable theoretical and clinical diversity, inadequate reporting of intervention procedures, methodological flaws, and few replication studies. The evidence for a positive effect of interventions for general bereaved populations is also weak. Our review did not address the question of whether interventions for people bereaved through suicide need to be different from those provided to people bereaved through other means. Given the limitations of the studies of general bereaved populations and populations bereaved through suicide, it is unlikely that data are currently available to address this question. However, it is an important issue that should be addressed.

Implications for practice and research

The evidence we have identified and appraised is not robust; clear implications for practice therefore cannot be drawn. However, based on the limited evidence available from single studies, the following tentative suggestions are made: psychologist-led group therapy for children may reduce anxiety and depression, and combined health professional- and volunteer-led group therapy for adults may reduce feelings of anger towards the deceased and self, anxiety, depression, grief, guilt, puzzlement and shame. There is also recent evidence that a brief CBT family intervention by a trained psychiatric nurse counsellor resulted in fewer maladaptive grief reactions and less self-blame. However, it remains unclear whether interventions are helpful and, if they are, the best timing of such intervention. Similarly, it is unclear whether they are helpful for all people bereaved through suicide or whether there are specific individuals who might benefit most – for example those experiencing complicated grief.

The views of participants were noticeably absent from the studies. Their views on the interventions received were generally not obtained and it was unclear whether the support given was viewed as helpful and appropriate to their needs. Obtaining the views of participants in future studies is vital to help identify the effective components of interventions and to establish what support is helpful to people bereaved by suicide. Grief can be culture-specific; consideration needs to be given to the generalisability of evidence to different ethnic groups. Research is required on the effectiveness of interventions in different ethnic groups as well as the potentially different responses of males and females, people of different ages and background as well as those experiencing complicated grief.

There is a pressing need for methodologically sound RCTs. Although this is a challenging study design to implement in this field, the recently published trial of CBT illustrates that it is possible. Sample size calculations need to take into account the need for analysis to investigate the impact of potentially important prognostic factors on outcome. It would aid meaningful comparison between studies if a core set of outcome measures could be used; consideration needs to be given to whether to use generic scales for anxiety and depression and/or grief specific measures.
